INTRODUCTION

Ultrasound imaging is increasingly used with motion and force data to quantify tendon dynamics and to understand the functional role of tendons during human and other animal movement. Frequently, tendon dynamics are estimated indirectly from measures of muscle kinematics (by subtracting muscle length from muscle-tendon unit length), but there is mounting evidence that this approach, which we term the *Indirect* method, yields implausible tendon work loops (tendon force vs. elongation) [e.g., 1-2]. Since tendons are passive, viscoelastic structures, they should exhibit negative work loops (i.e., net negative work over a loading-unloading cycle). However, prior studies using Indirect estimates of tendon kinematics report large positive work loops, estimating that tendons return 100-400% more energy than they store [e.g., 1-2]. More direct ultrasound methods have emerged that estimate tendon elongation by tracking either the muscle-tendon junction (termed the *Direct MTJ* method) or localized tendon tissue stretch (termed the *Direct Tendon* method) [3]. However, it is unclear if these Direct estimates yield more plausible tendon work loops. Here, we estimated tendon work loops and hysteresis using these two Direct tendon kinematics estimates during human walking compared to previously reported values based on Indirect kinematics estimates.

METHODS

We reanalyzed human walking data from our prior work (N=8, mean ± standard deviation, age: 23.9 ± 4.6 years) [3]. Subjects completed two 2-minute walking trials at three walking speeds (0.75, 1.00, and 1.25 m/s) - one trial for each of two probe locations. We collected human motion and force data using standard gait analysis procedures. Simultaneously, we collected raw radiofrequency (RF) data from longitudinal cross-sections through the right plantarflexor MTU using a 10-MHz, 38-mm linear array transducer (L14-5W/38, Ultrasonix, Richmond, BC) secured using an orthotic. For the Direct MTJ estimate, we recorded (128 frames/s) through a 3 cm depth from a probe centered on the distal lateral gastrocnemius (LG) MTJ, from which we estimated local MTJ displacements. For the Direct Tendon estimate, we recorded (155 frames/s) through a 2 cm depth from a probe on the distal free Achilles tendon. Custom 2D speckle-tracking estimated longitudinal free Achilles tendon tissue displacements [3]. Achilles tendon elongations were then derived by co-registering local LG MTJ (Direct MTJ) and Achilles free tendon (Direct Tendon) displacements with the calcaneus marker position. Finally, we estimated Achilles tendon force as the net ankle moment divided by subject-specific measures of the Achilles tendon moment arm to create stance phase tendon work loops (tendon force vs. elongation). We integrated tendon work loops to calculate: (i) net stance phase work (J) and (ii) hysteresis (%), defined as one minus the positive work (energy returned during tendon unloading) divided by negative work (energy stored during loading). Tendon hysteresis from Direct MTJ and Direct Tendon methods were compared to Indirect values from literature [e.g., 1-2]

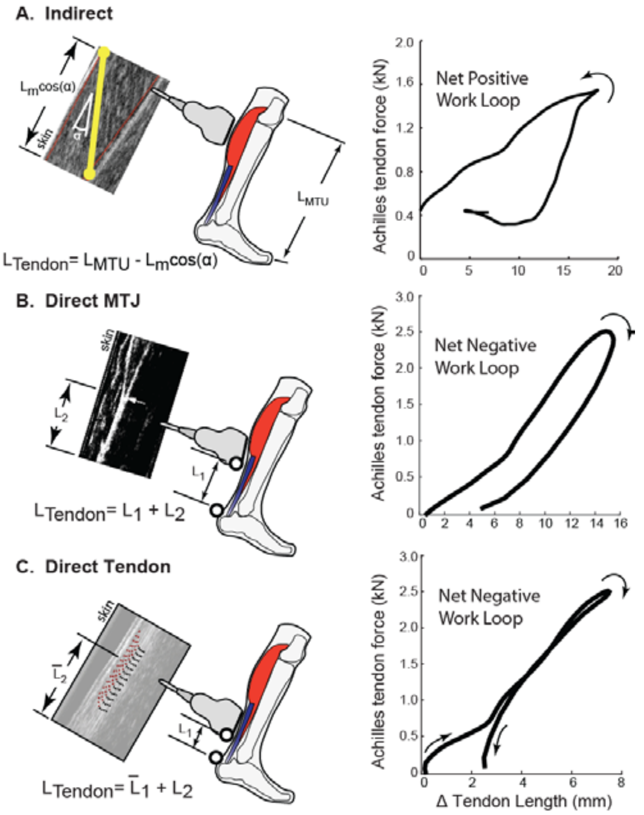

Figure 1. Tendon kinematic measurements and group-average tendon work loops during walking.

RESULTS AND DISCUSSION

Based on digitized data from literature, Achilles tendon hysteresis during walking derived indirectly from soleus and gastrocnemius fascicle kinematics elicited values of approximately -130% and -200%, respectively, indicating considerable but physiologically implausible positive work performed by the tendon (Fig. 1A) [1]. In contrast to Indirect estimates, we found that both Direct methods yielded, on average, negative tendon work loops and thus positive tendon hysteresis values during the stance phase of walking. Direct MTJ tendon hysteresis (net work) averaged 49.7% (-8.9 J), 37.9% (-8.2 J), and 9.2% (-5.1 J) for walking at 0.75, 1.00, and 1.25 m/s, respectively (Fig. 1B). Direct Tendon estimates averaged 32.9% (-3.4 J), 11.0% (-2.0 J), and 2.1% (-1.2 J), respectively (Fig. 1C).

CONCLUSIONS

As we advance our scientific understanding of movement biomechanics, it is important to continue advancing and validating our experimental methods. Compared to Indirect tendon estimates, Direct estimates may be preferable for understanding tendon dynamics such as energy storage and return, especially during dynamic activities such as walking.
